SUMMARY

This paper is dedicated to the identification of constitutive parameters of elasto-viscoplastic constitutive law from measurements performed on deep underground cavities (typically tunnels). This inverse problem is solved by the minimization of a cost functional of least square type. The exact gradient is computed by the direct differentiation method and the descent is done using the Levenberg-Marquardt algorithm. The method is presented for lined or unlined structures and is applied for an elastoviscoplastic constitutive law of the Perzyna class. Several identification problems are presented in one and two dimensions for different tunnel geometries. The used measurements have been obtained by a preliminary numerical simulation and perturbed with a white noise. The identified responses matches the measurements. We also discuss the usage of the sensitivity analysis of the system, provided by the direct differentiation method, for the optimization of in situ monitoring. The sensitivity distribution in space and time assess the location of the measurements points as well as the time of observation needed for reliable identification. 1. INTRODUCTION

It is well known that underground structures located in salt, hard marls etc... present important time dependent deformations even dozens of years after the excavation. Several examples of case histories can be found in the litterature: large delayed displacement have been reported in motorway tunnels [1], or long term subsidence have been observed over salt caverns [2]. A series of industrial problems involving deep cavities, like the storage of radioactive waste depend on the characterization of suchs effects in order to assess the safety of the overall project.

These time dependent observations are generally explained by several phenomena: hydro-mechanical couplings [3] and/or rate dependent mechanical behavior [4, 5]. Predictive models are classically proposed from a series of laboratory test. Unfortunately in many cases there is

still a discrepancy between predictions and measurements when one passes from the laboratory to the field.

These discrepancies can be justified by a series of factors: scale effects, uncertainties on the constitutive model itself, on the identified parameters of the chosen constitutive law, etc. It is obvious, that it is preferable to correct the constitutive parameters using the first measurements already available, before any long term extrapolation of the model.

The problem addressed in this paper is the identification (or correction) of the constitutive parameters from field measurements. The work presented here is a further attempt to propose a systematic method to reduce the gap between field observations and computations performed with the parameters identified from results of laboratory tests.

The problem of parameter identification is an inverse problem [6, 7], also known as back-analysis. In general, the problem is defined as the minimization of a cost functional measuring the distance between measurements and predictions. A large review of back analyses methods in geotechnical engineering is presented in Sakurai [8].

Next we shall only refer to gradient based minimizations, however it is important to notice that a large class of evolutionary methods (genetic algorithms, neural networks, etc.) have been proposed recently in the literature. Our choice is justified on the one hand by the computational burden of the evolutionary methods and on the other hand by the form of the cost functional in the explored parameter space.

Most of the results in geotechnics have been obtained in the case of linear material behaviour [9, 10, 11]. This is mainly due to the computational burden and the intrinsic complexity of the inverse procedure for the non-linear behaviour. A small number of papers deal with an elastoplastic constitutive law. They generally use an optimization procedure without gradient [12] due to the difficulties of the differentiation of the elastoplastic inequalities.

When the gradients are provided by the *finite difference method*, we dispose only of an *approximate* value. Moreover, it is well known that this method presents two main drawbacks, one comes from the difficult choice of the stepsize in computing the difference and the other one stems from the large number of nonlinear problems which have to be solved.

Recently a series of papers (for a general introduction see [13]) have shown that one can solve the identification problems using an *exact* gradient computation as compared with finite differences. The exact gradient is obtained here by solving a series of additional problems and two methods have been widely used:

- in the *adjoint state method* one constructs a single additional problem, the so called adjoint problem which is linear, i.e. viscoelastic, and has to be integrated backwards in time. The solution of the direct problem and of the adjoint problem determines the exact value of the gradient, independent of the number of parameters in the minimization process.

An example of a solution for the case of an elastoviscoplastic law can be found in [14].

- in the *direct differentiation method* one constructs an additional problem for each parameter involved in the minimization process, which is linear, i.e. viscoelastic, and has to be integrated forward in time. Thus the local sensitivities of all fields with respect to all parameters is obtained and can be used for the optimization.

This methods has been previously used in a series of papers by Vidal et al. [15, 16], Tsay & Arora [17], Galarza et al. [18] in order to solve optimization problems.

In the sequel we shall present a solution to the identification problem of material

parameters in the case of underground structures using the direct differentiation method. An important step is the coupling of the sensitivity analysis with the numerical modeling of the tunneling process including the setup of the lining. As a first approach we shall neglect the hydromechanical coupling and focus just on the mechanical behaviour of the rockmass. We refer to Bérest [4] and Cristescu [5] for a complete review of the viscoplasticity of rocks.

In a first part the direct differentiation method is derived for elastoviscoplastic constitutive law of the Perzyna type [19] following the steps of Vidal et al. [15]. In a second part, the method is tested on a series of examples for a Norton-Hoff material law using simulated measurements.

The results obtained using a Levenberg-Marquardt minimization show that the method is robust and efficient. However certain questions about the uniqueness and stability of the inverse problem also arise.

In the last part we shortly discuss the usage of the sensitivity analysis of the system for the optimization of in situ monitoring. The sensitivity distribution of the mechanical fields in space and time assess the location of the measurements points as well as the time of observation needed for reliable identification.

2. THE LINED TUNNEL AND THE ASSOCIATED INVERSE PROBLEMS

Let us consider the following time interval $T = [0, t_f]$ during which the tunnel will be excavated, supported and monitored. The lining will be installed at $t = t_\ell$.

The domain of interest Ω evolves during this period in the following way :

- initially, for $t \in [-\infty, 0]$, Ω is the *nonexcavated domain*;
- then, for $t \in [0, t_\ell]$ the domain $\Omega = \Omega_X$ represents the rock mass with the excavated tunnel before the installation of the lining;
- finally, for $t > t_\ell$, the domain $\Omega = \Omega_X \cup \Omega_\ell$ is the excavated rock mass together with the lining of the tunnel.

The border $\Gamma = \partial\Omega$ of the complete domain Ω is divided in two sets Γ_t and Γ_u on which tractions and displacements are respectively prescribed. The interface between the lining and the rock mass will be denoted $\Gamma_{X\ell}$.

Let \mathbf{u} , $\boldsymbol{\epsilon}$ and $\boldsymbol{\sigma}$ stand for the displacement, the small strain operator and the Cauchy stress tensor respectively.

2.1. The Direct Problem \mathcal{P}

Before excavation, at time $t = 0$, we shall assume that the rock mass is in its natural state given by the initial statically admissible stress state :

$$\boldsymbol{\sigma} = \boldsymbol{\sigma}_0 \tag{1}$$

and that all the other mechanical fields are equal to zero. The evolution of the rockmass is described by the following system of equations, written in rate form as:

- Balance equation on $\Omega \times T$ and imposed tractions on the boundary on $\Gamma_t \times T$:

$$\begin{cases} \operatorname{div} \dot{\boldsymbol{\sigma}} + \dot{\mathbf{f}} = 0 \\ \dot{\boldsymbol{\sigma}} \mathbf{n} = \dot{\mathbf{t}}^d \end{cases} \tag{2}$$

- Small strain equations on $\Omega \times T$ and displacement boundary conditions on $\Gamma_u \times T$:

$$\begin{cases} \varepsilon(\dot{\mathbf{u}}) = \frac{1}{2} (\nabla \dot{\mathbf{u}} + \nabla^T \dot{\mathbf{u}}) \\ \dot{\mathbf{u}} = \dot{\mathbf{u}}^d \end{cases} \quad (3)$$

- Elastoviscoplastic constitutive law of Perzyna class [19] for the rock mass on $\Omega_X \times T$:

$$\begin{cases} \dot{\boldsymbol{\sigma}} = \mathbf{C} : (\dot{\boldsymbol{\varepsilon}} - \dot{\boldsymbol{\varepsilon}}^{vp}) \\ \dot{\boldsymbol{\varepsilon}}^{vp} = \frac{\partial \phi(\boldsymbol{\sigma})}{\partial \boldsymbol{\sigma}} \end{cases} \quad (4)$$

where ϕ is a pseudo-potential functional of the stress tensor [19].

The expression of ϕ for the Norton-Hoff law is given by :

$$\phi(\boldsymbol{\sigma}) = \frac{K}{N+1} \left\langle \frac{\sigma_{eq} - \sigma_Y}{K} \right\rangle^{N+1} \quad (5)$$

where :

- σ_{eq} is the Von Mises equivalent stress ($[ML^{-1}T^{-2}]$);
- σ_Y the yield limit ($[ML^{-1}T^{-2}]$);
- N the viscoplastic exponent ($[]$);
- K the viscosity coefficient ($[ML^{-1}T^{-2+1/N}]$).

- Elastic behaviour for the lining on $\Omega_\ell \times]t_l, t_f]$:

$$\dot{\boldsymbol{\sigma}} = \mathbf{C}_l : \dot{\boldsymbol{\varepsilon}} \quad (6)$$

The constitutive law is fairly simple, but includes several interesting features: a cohesion and highly nonlinear viscosity. A series of classical characteristics such as plastic dilatancy or hardening/softening effects are not included. This material behavior allows to reproduce the shape of the classically observed delayed convergence of tunnel excavated in viscoplastic rocks.

In rocksalt mechanics, it is largely accepted that the material behaves like a viscous fluid. The non newtonian Norton or Lemaitre-Menzel-Schreiner constitutive laws are frequently used in applications [20]. Other viscous rocks such as shales or marls cannot be considered as viscous fluids and a long term resistance must be accounted for. In this case, the larger class of viscoplastic constitutive laws of Perzyna type has been proposed by many authors [21, 1]. The Norton-Hoff law used here for illustration, permits a direct extension accounting for strain hardening (or softening) and internal friction.

The numerical integration of the initial boundary value problem is classically done by finite elements in space and finite difference in time. An extensive presentation of these techniques is given in [22].

At this point let us recall the weak formulation of the preceding problem which will be used in the sequel for the description of the direct differentiation method. On the discretized time interval $[t_n, t_{n+1}]$, the weak formulation at time $t = t_{n+1}$ can be written using a forward Euler (implicit) scheme for the time integration and a radial return mapping for the local plastic integration [22]:

Find $\mathbf{u}_{n+1} \in \mathcal{U}$, ε_{n+1}^{vp} and $\boldsymbol{\sigma}_{n+1}$ satisfying :

$$\int_{\Omega} \varepsilon(\mathbf{v}) : \boldsymbol{\sigma}_{n+1} d\Omega - \int_{\Omega} \mathbf{v} \mathbf{f}_{n+1} d\Omega - \int_{\Gamma_t} \mathbf{v} \mathbf{t}_{n+1}^d d\Gamma = 0 \quad \forall \mathbf{v} \in \mathcal{V} \quad (7)$$

$$\boldsymbol{\sigma}_{n+1} = \mathbf{C} : (\varepsilon(\mathbf{u}_{n+1}) - \varepsilon_{n+1}^{vp}) + \boldsymbol{\sigma}_0 \quad (8)$$

$$\varepsilon_{n+1}^{vp} = \varepsilon_n^{vp} + \Delta t_{n+1} \frac{\partial \phi(\boldsymbol{\sigma}_{n+1})}{\partial \boldsymbol{\sigma}} \quad (9)$$

where all fields $X(t_{n+1})$ at time $t = t_{n+1}$ are noted X_{n+1} and $\Delta t_{n+1} = t_{n+1} - t_n$.
 \mathcal{U} and \mathcal{V} are the classical functional space :

$$\begin{cases} \mathcal{U} = \{ \mathbf{u} \in H^1(\Omega) \mid \mathbf{u}_{n+1} = \mathbf{u}^d(t_{n+1}) \text{ on } \Gamma_u \} \\ \mathcal{V} = \{ \mathbf{v} \in H^1(\Omega) \mid \mathbf{v} = 0 \text{ on } \Gamma_u \} \end{cases} \quad (10)$$

We recall that $\boldsymbol{\sigma}_0$ denotes the in situ stresses field.

Let us now discuss the computational details imposed by the excavation of the tunnel and the installation of the lining. The FEM computations will be performed on the domain $\Omega_X \cup \Omega_\ell$ for all time steps. Before the effective installation of the lining, the mechanical influence of Ω_ℓ has to be neglected and therefore the Young moduli of the lining has been chosen such that $E_l \ll E_m$.

The different steps can now be described in the following way:

- For $t \in [-\infty, 0]$, the nonexcavated domain is at equilibrium with an initial stress state. The FEM boundary condition should be: $\boldsymbol{\sigma} \cdot \mathbf{n}|_{\Gamma_\ell} = \boldsymbol{\sigma}_0 \cdot \mathbf{n}$. Due to the negligible stiffness in Ω_ℓ this is practically equivalent with the real condition: $\boldsymbol{\sigma} \cdot \mathbf{n}|_{\Gamma_{X\ell}} = \boldsymbol{\sigma}_0 \cdot \mathbf{n}$.
- For $t \in [0, t_\ell]$: The tunnel is already excavated but the lining is not active. The boundary Γ_{Xl} of the rock mass is free of traction. Using the same argument as before, we impose: $\boldsymbol{\sigma} \cdot \mathbf{n}|_{\Gamma_\ell} = \mathbf{0}$ Due to the negligible stiffness in Ω_ℓ this is practically equivalent with the real condition: $\boldsymbol{\sigma} \cdot \mathbf{n}|_{\Gamma_{X\ell}} = \mathbf{0}$.
- For $t \in [t_\ell, t_f]$, the elastic lining is set. The boundary condition is now: $\boldsymbol{\sigma} \cdot \mathbf{n}|_{\Gamma_\ell} = \mathbf{0}$ However, at this point the stiffness of the lining is not negligible anymore and therefore the traction between lining and rockmass expressed by $\boldsymbol{\sigma} \cdot \mathbf{n}|_{\Gamma_{X\ell}}$ is no more zero.

Here, we supposed that an instantaneous deconfinement is applied at the tunnel wall to simulate the excavation process. This is justified by the fact that excavation period, typically some weeks, is negligible with respect to the period of interest, typically 10 to 50 years. An extended discussion supporting these assumptions from the geotechnical point of view can be found in [23].

Taking into account a complicated history of deconfinement does not change fundamentally our approach, but for the sake of simplicity this problem will not be addressed thereafter.

2.2. The Inverse Problem \mathcal{P}^{-1}

In the inverse problem, we shall consider that the constitutive parameters are unknown. This drawback will be supplemented with a series of measurements, for example:

- convergence of the tunnel wall;

- displacement measurements, by extensometers, within the rock mass;
- pressure cells, measuring the contact force between the lining and the rock mass.

A general formulation of this identification problem is:

Find $\mathbf{c} = \{E, N, \sigma_Y, K\}$ from displacements and forces measurements performed during the time interval T .

From a mathematical point of view, this problem can be recasted as the minimization of a cost functional measuring the gap between measurements and the direct estimations.

In order to solve this problem two issues have to be addressed:

- Choice of the cost functional
- Choice of the minimization algorithm

In our case we have chosen to minimize the classical weighted least squares functional:

$$\begin{aligned} \mathcal{J}(\mathbf{c}) &= \frac{1}{2} \sum_{i=1,k} \sum_{j=1,p} \left(\frac{\mathbf{u}(\mathbf{c}, t_i, \mathbf{x}_j) - \mathbf{u}_{mes}(t_i, \mathbf{x}_j)}{w_{u_{ij}}} \right)^2 \\ &+ \frac{1}{2} \sum_{i=1,k} \sum_{j=1,p} \left(\frac{\mathbf{t}(\mathbf{c}, t_i, \mathbf{x}_j) - \mathbf{t}_{mes}(t_i, \mathbf{x}_j)}{w_{t_{ij}}} \right)^2 \end{aligned} \quad (11)$$

where \mathbf{u} and \mathbf{t} are displacements and tractions computed by direct computations, \mathbf{u}_{mes} and \mathbf{t}_{mes} are measured quantities, t_i, \mathbf{x}_j are respectively the time instants and the location of the measurements, w_t and w_u are weights.

The gradient of the preceding cost functional can be written as:

$$\begin{aligned} \frac{\partial \mathcal{J}}{\partial c_l} &= \sum_{i=1,k} \sum_{j=1,p} \frac{\mathbf{u}(\mathbf{c}, t_i, \mathbf{x}_j) - \mathbf{u}_{mes}(t_i, \mathbf{x}_j)}{w_{u_{ij}}^2} \frac{\partial \mathbf{u}}{\partial c_l}(\mathbf{c}, t_i, \mathbf{x}_j) \\ &+ \sum_{i=1,k} \sum_{j=1,p} \frac{\mathbf{t}(\mathbf{c}, t_i, \mathbf{x}_j) - \mathbf{t}_{mes}(t_i, \mathbf{x}_j)}{w_{t_{ij}}^2} \frac{\partial \mathbf{t}}{\partial c_l}(\mathbf{c}, t_i, \mathbf{x}_j) \end{aligned} \quad (12)$$

In the sequel we shall use the *direct differentiation method* to compute the gradient. More precisely, this method allows to compute exactly not only $\frac{\partial \mathcal{J}}{\partial \mathbf{c}}$ as in the *adjoint state method* but also the values of the sensitivities of all mechanical fields $\frac{\partial \mathbf{u}}{\partial c_l}, \frac{\partial \boldsymbol{\sigma}}{\partial c_l}, \dots$ in each point and at each instant. This method requires the solution of n additional viscoelastic problems, where n is the number of parameters. This method will be described in the next section.

3. SENSIVITY ANALYSIS

We will describe the Direct Differentiation Method for a general set of parameter $\mathbf{c} = (c_1, \dots, c_i, \dots)$ and consider the particular case of constitutive parameters at the end. The direct differentiation of the classical initial boundary problem in elasto-viscoplasticity will rise a somehow similar system of partial differential equations, where the constitutive equation is

always similar to a viscoelastic law. The unknown functions of these problems are $\delta_{c_i} \mathbf{u}$ and $\delta_{c_i} \boldsymbol{\sigma}$. They represent respectively the gradients $\frac{\partial \mathbf{u}}{\partial c_i}$ and $\frac{\partial \boldsymbol{\sigma}}{\partial c_i}$.

The differentiation of the equilibrium and compatibility equations are straightforward since the divergence and gradient are linear operators. The boundary and initial conditions are also easily derived. In particular, if the boundary conditions do not depend on the constitutive parameters c_i , the sensitivity problem has homogeneous boundary conditions.

3.1. Differentiation of the discretized constitutive law

The pseudo potential is a function of the parameters c_i and the stress field also depends on c_i . Therefore we have : $\phi(\boldsymbol{\sigma}(c_i), c_i)$.

The differentiation of equation (5) and (4) thus gives :

$$\begin{aligned} \delta_{c_i} \boldsymbol{\sigma}_{n+1} &= \frac{\partial \mathbf{C}}{\partial c_i} : (\boldsymbol{\varepsilon}(\mathbf{u}_{n+1}) - \boldsymbol{\varepsilon}_{n+1}^{vp}) \\ &+ \mathbf{C} : (\boldsymbol{\varepsilon}(\delta_{c_i} \mathbf{u}_{n+1}) - \delta_{c_i} \boldsymbol{\varepsilon}_{n+1}^{vp}) + \frac{\partial \boldsymbol{\sigma}_0}{\partial c_i} \end{aligned} \quad (13)$$

$$\delta_{c_i} \boldsymbol{\varepsilon}_{n+1}^{vp} = \delta_{c_i} \boldsymbol{\varepsilon}_n^{vp} + \Delta t_{n+1} \frac{\partial^2 \phi(\boldsymbol{\sigma}(c_i), c_i)}{\partial \boldsymbol{\sigma} \partial c_i} + \Delta t_{n+1} \frac{\partial^2 \phi(\boldsymbol{\sigma}_{n+1})}{\partial \boldsymbol{\sigma}^2} \delta_{c_i} \boldsymbol{\sigma}_{n+1} \quad (14)$$

Combining the last equations we can derive the following constitutive law for the sensitivity fields:

$$\begin{aligned} \delta_{c_i} \boldsymbol{\sigma}_{n+1} &= \boldsymbol{\Xi}_{n+1} : \boldsymbol{\varepsilon}(\delta_{c_i} \mathbf{u}_{n+1}) \\ &+ \boldsymbol{\Xi}_{n+1} : \left[\mathbf{C}^{-1} : \frac{\partial \mathbf{C}}{\partial c_i} : (\boldsymbol{\varepsilon}(\mathbf{u}_{n+1}) - \boldsymbol{\varepsilon}_{n+1}^{vp}) \right] \\ &+ \boldsymbol{\Xi}_{n+1} : \left[\mathbf{C}^{-1} : \frac{\partial \boldsymbol{\sigma}_0}{\partial c_i} - \delta_{c_i} \boldsymbol{\varepsilon}_n^{vp} - \frac{\partial^2 \phi(\boldsymbol{\sigma}_{n+1}(c_i), c_i)}{\partial \boldsymbol{\sigma} \partial c_i} \Delta t_{n+1} \right] \end{aligned} \quad (15)$$

Where $\boldsymbol{\Xi}_{n+1}$ is the consistent tangent operator [22, 15] defined by :

$$\boldsymbol{\Xi}_{n+1} = \left(\mathbf{C}^{-1} + \Delta t_{n+1} \frac{\partial^2 \phi(\boldsymbol{\sigma}_{n+1})}{\partial \boldsymbol{\sigma}^2} \right)^{-1} \quad (16)$$

This constitutive relation is of the visco-elastic type, the response of the stress sensitivity at time t_{n+1} depends linearly on the displacement sensitivity at time t_{n+1} and known sensitivities at t_n .

3.2. Weak form of the sensitivity problem \mathcal{P}^s

Following a similar method as in the direct problem (??), the initial boundary value problem on the sensitivity can be written in the following weak form :

Find $\delta_{c_i} \mathbf{u}_{n+1} \in \mathcal{W}$ and $\delta_{c_i} \boldsymbol{\sigma}_{n+1}$ satisfying :

$$\int_{\Omega} \varepsilon(\mathbf{v}) : \delta_{c_i} \boldsymbol{\sigma}_{n+1} d\Omega - \int_{\Omega} \mathbf{v} \frac{\partial \mathbf{f}_{n+1}}{\partial c_i} d\Omega - \int_{\Gamma_t} \mathbf{v} \frac{\partial \mathbf{t}_{n+1}^d}{\partial c_i} d\Gamma = 0 \quad \forall \mathbf{v} \in \mathcal{W} \quad (17)$$

and the constitutive law on the sensitivity described by equation (15) mentioned above; together with the following initial conditions at time $t = 0$

$$\begin{aligned} \delta_{c_i} \boldsymbol{\sigma} &= \frac{\partial \boldsymbol{\sigma}_0}{\partial c_i} \\ \delta_{c_i} \mathbf{u} &= 0 \end{aligned} \quad (18)$$

\mathcal{W} is the space of admissible displacements defined by

$$\mathcal{W} = \left\{ \delta_{c_i} \mathbf{u} \in H^1(\Omega) \mid \delta_{c_i} \mathbf{u}_{n+1} = \frac{\partial \mathbf{u}_{n+1}^d}{\partial c_i} \text{ on } \Gamma_u \right\} \quad (19)$$

3.3. Incremental form of \mathcal{P}^s

To see the structure of the computation which is performed step by step, let us denote:

$$\delta_{c_i} \mathbf{u}_{n+1} = \delta_{c_i} \Delta \mathbf{u} + \delta_{c_i} \mathbf{u}_n \quad (20)$$

Therefore, the weak incremental formulation is :

$$\text{Find } \delta_{c_i} \Delta \mathbf{u} \in \mathcal{W} = \left\{ \delta_{c_i} \Delta \mathbf{u} \in H^1(\Omega) \mid \delta_{c_i} \Delta \mathbf{u} = \frac{\partial \Delta \mathbf{u}^d}{\partial c_i} \text{ on } \Gamma_u \right\} \text{ and } \delta_{c_i} \boldsymbol{\sigma}_{n+1} \text{ satisfying :}$$

$$\begin{aligned} \int_{\Omega} \varepsilon(\mathbf{v}) : \boldsymbol{\Xi}_{n+1} : \varepsilon(\delta_{c_i} \Delta \mathbf{u}) d\Omega &= \int_{\Omega} \mathbf{v} \frac{\partial \mathbf{f}_{n+1}}{\partial c_i} d\Omega + \int_{\Gamma_T} \mathbf{v} \frac{\partial \mathbf{t}_{n+1}^d}{\partial c_i} d\Gamma \\ &+ \int_{\Omega} \varepsilon(\mathbf{v}) : \boldsymbol{\Xi}_{n+1} : \frac{\partial^2 \phi(\boldsymbol{\sigma}_{n+1}(c_i), c_i)}{\partial \boldsymbol{\sigma} \partial c_i} \Delta t_{n+1} d\Omega \\ &- \int_{\Omega} \varepsilon(\mathbf{v}) : \boldsymbol{\Xi}_{n+1} : \mathbf{C}^{-1} : \frac{\partial \mathbf{C}}{\partial c_i} : \left(\varepsilon(\Delta \mathbf{u}) - \Delta t_{n+1} \frac{\partial \phi(\boldsymbol{\sigma}_{n+1})}{\partial \boldsymbol{\sigma}} \right) d\Omega \\ &- \int_{\Omega} \varepsilon(\mathbf{v}) : \boldsymbol{\Xi}_{n+1} : \mathbf{C}^{-1} : \delta_{c_i} \boldsymbol{\sigma}_n d\Omega \quad \forall \mathbf{v} \in \mathcal{V} \end{aligned} \quad (21)$$

with the following constitutive law:

$$\begin{aligned} \delta_{c_i} \boldsymbol{\sigma}_{n+1} &= \boldsymbol{\Xi}_{n+1} : \varepsilon(\delta_{c_i} \Delta \mathbf{u}) \\ &+ \boldsymbol{\Xi}_{n+1} : \left[\mathbf{C}^{-1} : \delta_{c_i} \boldsymbol{\sigma}_n + \mathbf{C}^{-1} : \frac{\partial \mathbf{C}}{\partial c_i} : \left(\varepsilon(\Delta \mathbf{u}) - \Delta t_{n+1} \frac{\partial \phi(\boldsymbol{\sigma}_{n+1})}{\partial \boldsymbol{\sigma}} \right) \right] \\ &- \boldsymbol{\Xi}_{n+1} : \frac{\partial^2 \phi(\boldsymbol{\sigma}_{n+1}(c_i), c_i)}{\partial \boldsymbol{\sigma} \partial c_i} \Delta t_{n+1} \end{aligned} \quad (22)$$

and the initial conditions already mentioned in equation (18).

In the case where c_i is a constitutive parameter, the initial stresses and the imposed boundary conditions do not depend on c_i . Therefore, we have :

$$\begin{aligned} \frac{\partial \sigma_0}{\partial c_i} &= \mathbf{0} & \frac{\partial \mathbf{f}_{n+1}}{\partial c_i} &= \mathbf{0} \\ \frac{\partial \mathbf{t}_{n+1}^d}{\partial c_i} &= \mathbf{0} & \frac{\partial \mathbf{u}_{n+1}^d}{\partial c_i} &= \mathbf{0} \end{aligned}$$

The cost functional \mathcal{J} and its gradient $\nabla \mathcal{J}$ are computed from the solutions of the direct problem \mathcal{P} and of the sensitivities problems \mathcal{P}^S using equations (11) and (12).

4. THE FINITE ELEMENT PROGRAMING

The direct and sensitivity problem have been programmed in the object oriented finite element code CAST3M [24].

The direct problem has been solved using a radial return mapping for the plastic integration already implemented in the code (functions `ecoulement`, `pasapas`). The sensitivity problem has been solved including a programmed sequence at the end of each time step (using the `perso` facility of `pasapas` operator). Therefore space and time discretisation are the same for the direct and auxiliary problems as specified in [15]. A simple scheme of the time step computation is displayed in figure 1.

At the end of each time step, when convergence of the direct problem is achieved, the stiffness matrix of the direct problem is the consistent tangent operator given in equation (16). It can therefore be directly used in solving the sensitivity problems. At this point only the force terms arising in the sensitivity analysis have to be computed from already known fields (left hand side of equation (21)). If the stiffness matrix is stored in the LU decomposition, computations are fast. For the 4 sensitivities corresponding to the 4 parameters to be identified, the complete sensitivity analysis represented approximately half of the computational burden of the direct problem. This performance can still be enhanced provided that less fields are stored during the computation and that the time steps are optimized. This was however not a main objective of this work.

Let us now discuss shortly an important detail related to the setup of the lining. This procedure introduces a change of the domain as previously explained. The initial assumption is that one can consider the direct problem on the whole domain: lining + rock mass and neglect the influence of the lining using a vanishing Young's modulus before the setup of the lining. Theoretically, as all expressions are obtained between time steps on a fixed domain, the setup of the support does not influence the deduction of the sensitivity problem.

From a numerical point of view, the numerical value chosen for the vanishing Young's modulus did not influence the result of the direct problem. However for the computations of the sensitivities, we experienced that if the vanishing Young's modulus is chosen too small, i.e. $E_{\text{lining}} \ll 10^{-15} E_{\text{rock}}$, important errors are created at the first time step after the setup of the lining. These propagate in the sequel perturbing the solution. This can be explained by floating point errors in the algebraic manipulation in the left hand side of equation (21).

A Levenberg-Marquardt [25] algorithm has been used for the minimization procedure and programmed using the numerical package SCILAB developed at INRIA [26]. It is important

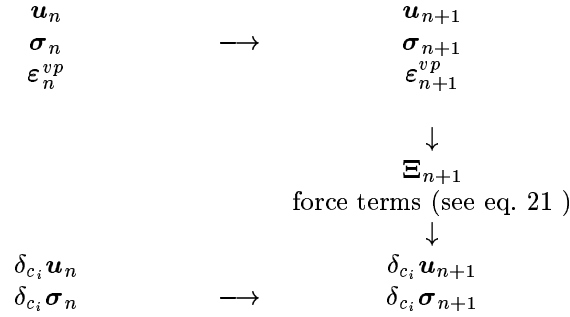

Figure 1. Scheme of a time step for the direct and sensitivity problem

to point out that the use of a singular value decomposition was necessary in the Levenberg-Marquardt algorithm in order to assure a robust estimate of the minimization step.

The computational time for the direct and sensitivity problem was less than 5 minutes for 1 iteration of the minimization algorithm (direct computation and direct differentiation problems) in a problem with 4460 degrees of freedom on a intel PentiumIII machine with 550MHz and 256MB RAM running under Linux.

5. RESULTS AND DISCUSSION

In this section we shall present a series of identifications based on simulated measurements. The “real” parameters \mathbf{c}_{real} , to be identified in the sequel, have been chosen in order to reproduce the order of magnitude found in situ and to be compatible with available experimental data on deep argileaceous rocks of Eastern France [27].

The first example presented correspond to a one dimensional problem with the following “real” parameter

$$E = 4.GPa \quad \nu = 0.3 \quad \sigma_Y = 1.MPa \quad N = 8. \quad K = 140MPa.s^{1/N}$$

and an isotropic initial stress state defined by:

$$\boldsymbol{\sigma}_0 = -12\mathbf{I} MPa$$

The second example corresponds to a two dimensional section of a tunnel, with:

$$E = 4.GPa \quad \nu = 0.3 \quad \sigma_Y = 3.MPa \quad N = 8. \quad K = 120MPa.s^{1/N}$$

and an anisotropic initial stress state:

$$\sigma_{vertical} = -12 MPa \quad \sigma_{Horizontal} = \sigma_{horizontal} = -9.6 MPa$$

The lining is supposed to have an elastic behavior with a Young’s Modulus of 15 GPa and a Poisson’s ratio of 0.25 corresponding to a reinforced concrete.

In both examples, we consider that displacements and contact forces are available as measurements at different locations on the lining and in the rock mass (see figure 5.2).

For the identification problem, we have considered a cost functional \mathcal{J} as defined in (11). The gradient $\nabla\mathcal{J}$ has been computed using (12). The weights $w_{u_{ij}}$ and $w_{t_{ij}}$ were considered equal for all measurements locations and were just adjusted to obtain a similar weight between the error in displacement and the error in force. The minimization procedure was performed using a preconditioning as explained in [25]. As a consequence $\|\nabla\mathcal{J}\|$ represents the euclidian norm of the preconditioned gradient of the cost functional.

5.1. One dimensional example

Let us consider the simple case of a circular tunnel of radius R in an infinite medium with isotropic initial stresses conducting to a one dimensional problem, in the lined and in the unlined case.

As mentioned before, the time of excavation is supposed to be negligible compared with the time of interest : the excavation is completed at $t = 0^+$. The lining, in the case of the supported cavity, is supposed to be set up approximately 20 days after the end of the excavation.

The measurements for the unlined tunnel are radial displacements at three different points in the rock mass : at the tunnel wall R , at $2R$ and respectively at $3R$ from the tunnel wall.

The measurements for the lined tunnel are convergence (radial displacements at the tunnel wall) and the contact force at the interface between the lining and the rock mass.

In all cases the optimal value of parameters (c_{real}) has been recovered after 10-20 iterations with an almost vanishing cost functional. This means that the final simulated results match the measurements as illustrated in figure 3 where 10% noise has been added to measurements.

A series of identified values for different starting points as well as the decrease of the value of the cost functional and of its gradient are represented in tables I and II for noiseless measurements. The values lie generally within 10% of the real value, with some exceptions for the unlined tunnel.

The number of measurement locations involved in the identification was not very important, similar results have been obtained with 1 or 3 set of displacement data.

The representation of the radial distribution of the sensitivities (see figures 2 and 5.1) can be linked with the ‘‘information content’’ of the mechanical fields with respect to the considered parameter. Thus it permits to decide the best measurement locations and observation periods for the identification.

Figure 2 shows that the strongest sensitivities on the displacements are contained in a region within $3R$ which corresponds to the viscoplastic zone. The sensitivity on the radial stress (see figure 5.1) is also concentrated in the viscoplastic zone, but the sensitivity maximum is located this time near the viscoplastic border in the rock mass.

The sensitivities are time increasing. However, for the lined tunnel (figure 4), the sensitivities reach an almost constant value with time. The time evolution of the sensitivities show that the lined and unlined problems have different characteristic times. This can be explained by the presence of a relatively stiff lining when compared with the rock mass ($E_{rock}/E_{lining} \approx 0.25$) and has already been interpreted from a geotechnical point of view by Bérest and Nguyen Minh [28].

The increase of the length of the observation period enhances, as expected, the accuracy of the identified parameters (see table IV).

Results for lined tunnels are generally more accurate (see tab. II). In this case the observation period is long enough for the structure to reach the steady state (figure 4) and contains

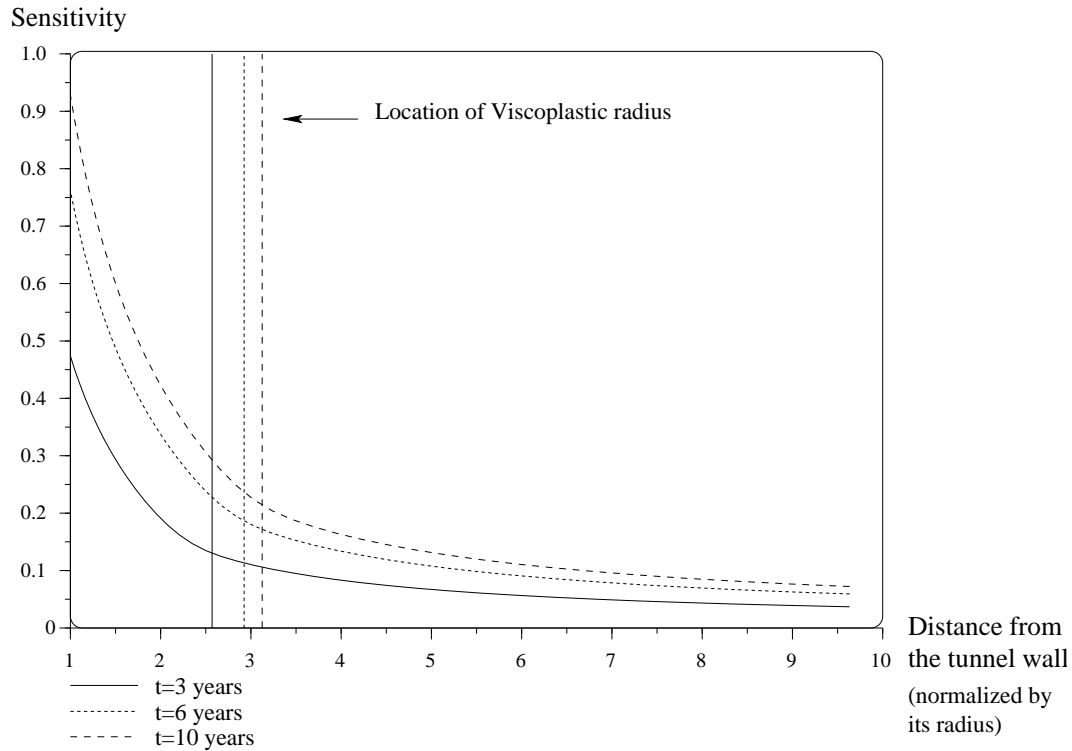

Figure 2. Sensitivity on Radial displacement $\delta_N u_r / R$, unlined tunnel (one dimensional).

therefore all the possible information. For unlined tunnels, the observation period is not long enough and this can explain the poor recovery of the optimum parameters in this case (see tab. I).

As a final remark, let us notice that the global shape of the sensitivity is similar for all constitutive parameters.

5.2. Two dimensional case

In the two dimensional case, the geometry of the tunnel and the corresponding finite element mesh as well as the location of the measurement are represented in figure 5.2.

In this case an anisotropic initial stress with $K_0 = 0.8$ has been considered. The excavation and lining sequence is the same as in the one dimensional case.

Like in the one dimensional case, the values have been recovered after a small number of iterations with an almost vanishing cost functional (see table V). A convergence example of

the parameters towards their “real value” is displayed in figure 6 in the case where the data were perturbed by a white noise of 10%.

The maximum spatial distribution of the sensitivity is located as in the one dimensional case, near the tunnel wall in the viscoplastic region (see figure 5.2). The sensitivity of radial stresses on the upper-vertical and horizontal radius (see figure 7) show profiles with are similar to the ones obtained for the one dimensional case (see figure 5.1).

The exact distribution of other components of the stresses will depend on the tunnel

Figure 7. profil of σ_{rr} and $\delta_N \sigma_{rr}$ in the two dimensional case ($K_0 = 0.8$).

geometry and on the initial stress state. The distribution of the von Mises stress as well as the von Mises norm of the sensitivity stress tensor are displayed in figure 5.2. One can remark a concentration around the diagonal directions which should be related with the ratio between the initial vertical and horizontal stresses. The sensitivity distributions permit to identify the optimal locations for installing the pressure cells, measuring the contact force, and the extensometers.

In the presented computations we have not observed an influence of the number of measurement locations on final results of the optimization. This might astonish in the first moment, but one has to recall that in the presented computation, sensitivity histories are similar in all locations. In the real case a data dispersion is to be expected coming on one hand from the noisy measurements and on the other hand from the inhomogeneity of the medium.

5.3. Uniqueness Discussion

The present results showed that in one and two dimensional configurations the parameters of the constitutive law could be reconstructed from contact forces and displacement measurements in the lining or in the rock mass. In all cases, measurements were matched almost perfectly,

Table VI. Results of the identification in the two dimensional case. No measurements inside the rock mass.

even if the estimated parameters were still at a certain distance from the real values. The question arising in such a case is that of the uniqueness of this inverse identification problem.

From a practical view, we have been plotting the variation of the cost functional in different planes. The shapes of the functional presented generally long flat valleys surrounding the optimum (see figure 9) in both lined and unlined cases showing that the optimum is always unique. In 9, we have displayed the shape of the cost functional in the plane $N - K$. The representation in the $\sigma_Y - E$ plane is similar.

The variations of the cost functional in this area are generally small and interfere with numerical noise. Similar behaviour has already been reported in [14].

The uniqueness observation could be related to a series of uniqueness proofs recently obtained in viscoelasticity [30, 29] for simple configurations. These mathematical results are obtained using an integrodifferential representation of the viscoelastic constitutive law and further work is needed to extend these results to the exact form of elastoviscoplasticity used

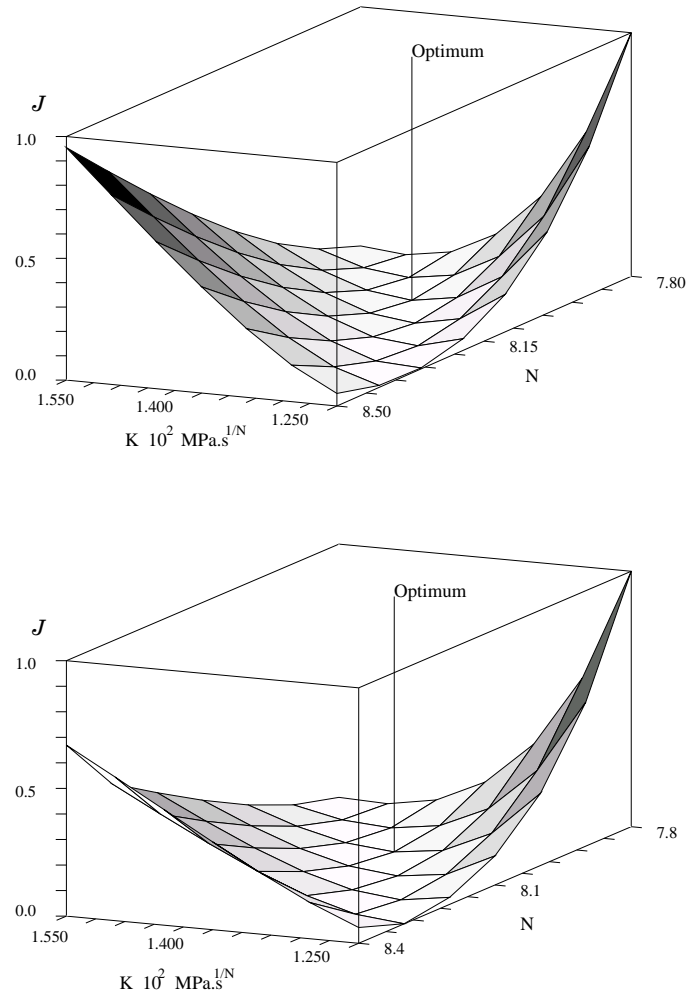

Figure 9. Three dimensionnal plot of the cost function in the plane $N - K$ for the one dimensional lined and unlined case.

here. The flat valley is to be related to a bad stability of the cost functional. Therefore, one should probably investigate other forms of cost functionals providing a better sensitivity with respect to the paramaters.

6. CONCLUSION

The present paper discussed the identification of constitutive parameters for an elastoviscoplastic law. The identification is based on a minimization algorithm and a gradient computed by direct differentiation. The constitutive parameters of the rockmass around an underground lined or unlined tunnel was obtained from simulated measurements, without using any a priori information or regularization techniques.

The results show that the direct differentiation method can be successfully applied in the particular case of tunneling. The installation of the lining and the subsequent modelling has not posed important difficulties.

The probabilistic character of measurements data and rock mass parameters can be included in the present method by adding covariances matrixes in the optimization process as explained in [7].

The obtained sensitivities also permit an optimization of the location of instrumentation in the rock mass and of the observation period. This is of particular interest in the context of in situ monitoring of underground structures.

The results of the different identification problem seem to confirm uniqueness conjectures and mathematical results obtained in viscoelasticity.

Further studies should include a larger range of constitutive equations and data coming from field measurements. Some preliminary results are reported in [31].

This study is part of an on-going research project sponsored by the French Nuclear Agency for Radioactive Waste Management (ANDRA), their support is gratefully acknowledged.

APPENDIX

Derivation of the sensitivities constitutive law

After eliminating $\delta_{c_i} \varepsilon_{n+1}^{vp}$ in equation (13) using (14), we obtained :

$$\begin{aligned} \delta_{c_i} \sigma_{n+1} &= \mathbf{C} : \left(\varepsilon(\delta_{c_i} \mathbf{u}_{n+1}) - \Delta t_{n+1} \frac{\partial^2 \phi(\sigma_{n+1})}{\partial \sigma^2} \delta_{c_i} \sigma_{n+1} \right) \\ &- \mathbf{C} : \left(\delta_{c_i} \varepsilon_n^{vp} + \Delta t_{n+1} \frac{\partial^2 \phi(\sigma(c_i), c_i)}{\partial \sigma \partial c_i} \right) \\ &+ \frac{\partial \mathbf{C}}{\partial c_i} : (\varepsilon(\mathbf{u}_{n+1}) - \varepsilon_{n+1}^{vp}) + \frac{\partial \sigma_0}{\partial c_i} \end{aligned}$$

Expressing $\delta_{c_i} \sigma_{n+1}$ as in functions of $\varepsilon(\delta_{c_i} \mathbf{u}_{n+1})$, we get :

$$\begin{aligned}
\underbrace{\left(\mathbf{C}^{-1} + \Delta t_{n+1} \frac{\partial^2 \phi(\boldsymbol{\sigma}_{n+1})}{\partial \boldsymbol{\sigma}^2} \delta_{c_i} \right)}_{\boldsymbol{\Xi}_{n+1}^{-1}} : \delta_{c_i} \boldsymbol{\sigma}_{n+1} &= \boldsymbol{\varepsilon}(\delta_{c_i} \mathbf{u}_{n+1}) \\
&- \delta_{c_i} \boldsymbol{\varepsilon}_n^{vp} + \Delta t_{n+1} \frac{\partial^2 \phi(\boldsymbol{\sigma}(c_i), c_i)}{\partial \boldsymbol{\sigma} \partial c_i} \\
&+ \mathbf{C}^{-1} : \frac{\partial \mathbf{C}}{\partial c_i} : (\boldsymbol{\varepsilon}(\mathbf{u}_{n+1}) - \boldsymbol{\varepsilon}_n^{vp}) \\
&+ \mathbf{C}^{-1} : \frac{\partial \boldsymbol{\sigma}_0}{\partial c_i}
\end{aligned}$$

Using the definition of the Consistent Tangent Moduli $\boldsymbol{\Xi}_{n+1}^{-1}$ (16), we easily get equation (15).
